Fragile X Syndrome and \textit{FMR1}-Associated Disorders

\textbf{Background}

Fragile X syndrome (OMIM\#300624) is the most common inherited cause of intellectual disability, with an incidence of approximately 1 in 4,000 males and 1 in 8,000 females. The syndrome was first recognized in 1977 when Sutherland linked a fragile site on the X chromosome with the phenotype of X-linked mental retardation and macroorchidism.\textsuperscript{1} The \textit{FMR1} gene was isolated in 1991 and PCR-based testing has since been used to make or confirm diagnoses of fragile X syndrome.\textsuperscript{2} In most cases, fragile X syndrome is caused by a trinucleotide (CGG) repeat expansion in the 5' untranslated (UTR) region of the gene. Normally, there are fewer than 45 CGG triplet repeats but affected individuals have greater than 200 CGG repeats. These full mutations of the CGG region result in hypermethylation of the promoter region, with subsequent silencing of gene expression and absence of the FMR1 protein (FMRP). Severity of symptoms of fragile X syndrome tend not to be affected by the number of trinucleotide repeats in the full mutation allele. However, individuals are less severely affected if they carry an unmethylated full mutation allele or are mosaic for the full and premutation alleles. About 30-50\% of females with full mutations are significantly affected.

Alleles with 55 to 200 CGG repeats are considered premutations; they do not cause fragile X syndrome but are prone to meiotic instability and may expand to full mutations in one generation. For reasons that are unclear, such expansions occur more often in female meiosis. Approximately 1 in 250 females is a carrier of an \textit{FMR1} premutation and at risk of having a child with fragile X syndrome.\textsuperscript{3} In addition, about 20\% of women with premutations experience primary ovarian insufficiency (POI), with onset of menopause before the age of 40.\textsuperscript{4}

Fragile X-associated tremor/ataxia syndrome (FXTAS), a late-onset neurodegenerative condition, has been identified as an \textit{FMR1}-related disorder. FXTAS is seen predominantly in men, with onset after 50 years of age. The penetrance among male premutation carriers increases with age, with 75\% showing symptoms by the ninth decade of life.\textsuperscript{5} Women also have a risk of developing FXTAS but with lower frequency and milder phenotype, due to random X-inactivation of the expanded allele. In contrast to the gene silencing that occurs in alleles with full mutations, premutations are associated with an up-regulation of transcription resulting in a toxic accumulation of \textit{FMR1} mRNA, usually in the presence of normal or slightly decreased protein levels. An intermediate, or “gray zone,” also exists in the \textit{FMR1} gene. Alleles containing 45 to 54 CGG repeats may also be unstable in meiosis but do not expand to full mutations in a single generation.

\textbf{Clinical Indications}

\textbf{Fragile X Syndrome:} The clinical phenotype associated with fragile X syndrome is variable and may be subtle in females. Therefore, the American College of Medical Genetics and Genomics (ACMG) suggests that testing be considered in all individuals with intellectual disability, developmental delay or autism, and especially in the presence of other fragile X characteristics or a family history of fragile X syndrome or undiagnosed intellectual disability.\textsuperscript{4}

\textbf{Primary Ovarian Insufficiency:} Further, ACMG and the American College of Obstetricians and Gynecologists (ACOG) recommend testing for women with evidence of primary ovarian insufficiency, i.e. infertility associated with elevated follicle stimulating hormone (FSH).\textsuperscript{4,6} As above, \textit{FMR1} testing should be considered when there is an accompanying family history of fragile X syndrome or undiagnosed intellectual disability, or if there is family history of primary ovarian failure.

\textbf{Fragile X Associated Tremor/Ataxia Syndrome:} \textit{FMR1} testing should also be considered in men and women with late onset...
Cerebellar ataxia and intention tremor, especially in the presence of family history of movement disorders, fragile X syndrome or undiagnosed intellectual disability.  

**Carrier Testing:** Reproductive carrier testing for fragile X syndrome is recommended for individuals with known family history of fragile X syndrome or with family history of undiagnosed intellectual disability. Population carrier screening for fragile X syndrome is not currently recommended due to the complex clinical implications of identifying expanded alleles.

**Methodology**

Determination of CGG expansion status is performed by PCR and capillary electrophoresis. PCR is performed on DNA isolated from peripheral blood using labeled primers designed to amplify the *FMR1* repeat region by triplet repeat primed-PCR assay (TP-PCR). PCR products are analyzed to determine the size(s) of the repeat expansion. This TP-PCR assay identified normal to full mutation *FMR1* alleles at 100% specificity and 97.4% sensitivity in a previous report.

*Based on recommendations of the ACMG Quality Assurance Committee and the Professional Practice and Guidelines Committee*.

Thorough interpretation of results is dependent on the indication for testing and relies on good communication of clinical information from the ordering provider. CGG repeats less than 45 are considered normal and are not consistent with a diagnosis of or risk for fragile X syndrome or any of the *FMR1*-related disorders. Individuals with alleles in the intermediate range of 45-54 CGG repeats would be expected to have a normal phenotype but future generations may be at risk for expansion of the repeat into the premutation or full mutation ranges. Individuals with premutations of 55-200 repeats generally do not have fragile X syndrome but are at risk of other *FMR1*-associated disorders, POI, or FXTAS. Premutation carrier females may have children with fragile X syndrome. Full mutations of greater than 200 CGG repeats are consistent with a diagnosis of fragile X syndrome but are not associated with increased risk of POI or FXTAS. Methylation studies may be ordered separately for samples with premutations and/or full mutations. In cases where the test results are not consistent with the clinical phenotype, additional testing may be required to assess other mutations in *FMR1*.

Due to the complex issues surrounding fragile X syndrome and *FMR1*-related disorders, documented informed consent and genetic counseling is recommended for all families undergoing testing. Informed consent forms need not be sent to this laboratory.
